**Abstract.** We present a cryptanalysis of a zero-knowledge identification protocol introduced by Naccache *et al.* at Eurocrypt '95. Our cryptanalysis enables a polynomial-time attacker to pass the identification protocol with probability one, without knowing the private key.

**Key Words:** Zero-knowledge, Fiat-Shamir Identification Protocol.

## 1 Introduction

An identification protocol enables a verifier to check that a prover knows the private key corresponding to a public key associated to its identity. A protocol is zero-knowledge when the only additional information obtained by the verifier is that the prover knows the corresponding private key [2]. A famous zero-knowledge identification protocol is Fiat-Shamir's protocol [1], which is provably secure assuming that factoring is hard. The protocol requires performing multiplications modulo an RSA modulus.

A space-efficient variant of the Fiat-Shamir identification protocol was introduced by Naccache [3] and by Shamir [5] at Eurocrypt' 94. This variant requires only a few bytes of RAM, even for an RSA modulus of several thousands bits, and is provably as secure as the original Fiat-Shamir protocol. This variant is particularly interesting when the prover is implemented in a smart-card, in which the amount of RAM is very limited.

However, the time complexity of the previous variant is still quadratic in the modulus size, and its implementation on a low-cost smart-card is likely to be inefficient. At Eurocrypt '95, Naccache *et al.* introduced another Fiat-Shamir variant [4]. It uses the same idea for reducing the space-complexity, but the prover's time complexity is now quasi-linear in the modulus size (instead of being quadratic). As shown in [4], the new

identification protocol can be executed on a low-cost smart-card in less than a second.

In this paper, we describe a cryptanalysis of one of [4]’s time-efficient variants. Our cryptanalysis enables a polynomial-time attacker to pass the identification protocol with probability one, without knowing the private key. We would like to stress that the basic quasi-linear time protocol introduced by [4] remains secure, since it is in fact equivalent to standard Fiat-Shamir and hence to factoring.

## 2 The Fiat-Shamir Protocol

We briefly recall Fiat-Shamir’s identification protocol [1]. The objective of the prover is to identify itself to any verifier, by proving knowledge of a secret  $s$  corresponding to a public value  $v$ , which is associated to its identity. The protocol is zero-knowledge in that it does not reveal any additional information about  $s$  to the verifier. The security relies on the hardness of factoring an RSA modulus.

**Key generation:** The authority generates a  $k$ -bit RSA modulus  $n = p \cdot q$ , and an integer  $v$  which is a function of the identity of the prover. Using the factorization of  $n$ , it computes a square root  $s$  of  $v$  modulo  $n$ , i.e.  $v = s^2 \pmod n$ . The authority publishes  $(n, v)$  and sends  $s$  to the prover.

### Identification protocol:

1. The prover generates a random  $x \leftarrow Z_n$ , and sends  $z = x^2 \pmod n$  to the verifier.
2. The verifier sends a random bit  $b$  to the prover.
3. If  $b = 0$ , the prover sends  $y = x$  to the verifier, otherwise it sends  $y = x \cdot s \pmod n$ .
4. The verifier checks that  $y^2 = z \cdot v^b \pmod n$ .
5. Steps 1-4 are repeated several time to reduce the cheating probability.

## 3 The Space-Efficient Variant of Fiat-Shamir’s Protocol

Fiat-Shamir’s protocol requires to perform multiplications modulo an RSA modulus  $n$ . It has a quadratic time and linear space complexity. Therefore, the original protocol could not be implemented on low-cost smart-cards, which in 1994 contained about 40 bytes of random access memory (RAM). Naccache [3] and Shamir [5] introduced a space-efficient variant which requires only a few bytes of RAM, even for an RSA modulus

of several thousands bits, and which is provably as secure as the original Fiat-Shamir protocol.

The idea is the following: assume that the prover is required to compute  $z = x \cdot y \bmod n$ , where  $x$  and  $y$  are two large numbers which are already stored in the smart-card (e.g., in its EEPROM<sup>1</sup>), or whose bytes can be generated on the fly. Then instead of computing  $z = x \cdot y \bmod n$ , the prover computes

$$z' = x \cdot y + r \cdot n$$

for a random  $r$  uniformly distributed in  $[0, B]$ , for a fixed bound  $B$ . The verifier can recover  $x \cdot y \bmod n$  by reducing  $z'$  modulo  $n$ . Moreover, when computing  $z'$ , the prover does not need to store the intermediate result in RAM. Instead, the successive bytes of  $z'$  can be sent out of the card as soon as they are generated. Therefore, a smart-card implementation of the prover needs only a few bytes of RAM (see [5] or [3] for more details).

As shown in [5], if  $B$  is sufficiently large, there is no loss of security in sending  $z'$  instead of  $z$ . Namely, from  $z$  one can generate  $z'' = z + u \cdot n$  where  $u$  is a random integer in  $[0, B]$ . Letting  $z = x \cdot y - \omega \cdot n$ , we have:

$$z'' = x \cdot y + (u - \omega) \cdot n$$

Then, the statistical distance between the distributions induced by  $z'$  and  $z''$  is equal to the statistical distance between the uniform distribution in  $[0, B]$  and the uniform distribution in  $[-\omega, B - \omega]$ , which is equal to  $\omega/B$ . Then, assuming that  $x$  and  $y$  are both in  $[0, n]$ , this gives  $\omega \in [0, n]$ , and the previous statistical distance is lesser than  $n/B$ . Therefore, by taking a  $B$  much larger than  $n$  (for example,  $B = 2^{k+80}$ , where  $k$  is the bit-size of  $n$ ), the two distributions are statistically indistinguishable, and any attack against the protocol using  $z'$  would be as successful against the protocol using  $z$ .

The identification protocol is then modified as follows:

#### Space-efficient Fiat-Shamir identification protocol:

1. The prover generates a random  $x \leftarrow Z_n$  and a random  $r \in [0, B]$ , and sends  $z = x^2 + r \cdot n$  to the verifier.
2. The verifier sends a random bit  $b$  to the prover.
3. If  $b = 0$ , the prover sends  $y = x$  to the verifier, otherwise it sends  $y = x \cdot s + t \cdot n$  for a random  $t \in [0, B]$ .

---

<sup>1</sup> The smart-card EEPROM is a re-writable memory, but the operation of writing is about one thousand time slower than writing into RAM, and can not be used to store fast-changing intermediate data during the execution of an algorithm.

4. The verifier checks that  $y^2 = z \cdot v^b \pmod n$ .
5. Steps 1-4 are repeated several time to reduce the cheating probability.

#### 4 The Time-Efficient Variant of Fiat-Shamir's protocol

The time complexity of the previous variant is still quadratic in the modulus size, and its implementation on a low-cost smart-card is likely to be inefficient. At Eurocrypt '95, Naccache *et al.* introduced yet another Fiat-Shamir variant [4]. It uses the same idea as Shamir's variant for reducing the space-complexity, but the prover's time complexity is now quasi-linear in the modulus size (instead of being quadratic). As shown in [4], the identification protocol can then be executed on a low-cost smart-card in less than a second.

The technique consists in representing the integers modulo a set of  $\ell$  small primes  $p_i$  (usually, one takes the first  $\ell$  primes). This is called the Residue Number System (RNS) representation. Letting  $\Pi = \prod_{i=1}^{\ell} p_i$ , by virtue of the Chinese Remainder Theorem, any integer  $0 \leq x < \Pi$  is uniquely represented by the vector:

$$(x \pmod{p_1}, \dots, x \pmod{p_\ell})$$

The advantage of this representation is that multiplication is of quasi-linear complexity (instead of quadratic complexity): if  $x$  and  $y$  are represented by the vectors  $(x_1, \dots, x_\ell)$  and  $(y_1, \dots, y_\ell)$ , then the product  $z = x \cdot y$  is represented by:

$$(x_1 \cdot y_1 \pmod{p_1}, \dots, x_\ell \cdot y_\ell \pmod{p_\ell})$$

The size  $\ell$  of the RNS representation is determined so that all integers used in the protocol are strictly smaller than  $\Pi$ ; the bijection between an integer and its modular representation is then guaranteed by the Chinese Remainder Theorem. The time-efficient variant of the Fiat-Shamir protocol is the following:

##### **Time-efficient variant of the Fiat-Shamir protocol:**

1. The prover generates a random  $x \in [0, n]$  and a random  $r \in [0, B]$ , and sends  $z = x^2 + r \cdot n$  to the verifier. The integers  $x$ ,  $r$  and  $z$  are represented in RNS.
2. The verifier sends a random bit  $b$  to the prover.
3. If  $b = 0$ , the prover sends  $y = x$  to the verifier, otherwise it sends  $y = x \cdot s + t \cdot n$  for a random  $t \in [0, B]$ . The integers  $x$ ,  $s$  and  $t$  are represented in RNS.

4. The verifier checks that  $y^2 = z \cdot v^b \pmod n$ .
5. Steps 1-4 are repeated several time to reduce the cheating probability.

The only difference between this time-efficient variant and Shamir's space-efficient variant is that integers are represented in RNS. Therefore, from a security standpoint, those variants are strictly equivalent.

However, another time-efficient variant is introduced in [4], whose goal is to increase the efficiency of the verifier. The goal of this second variant is to enable the verifier to check the prover's answer in linear time when  $b = 0$ . In this variant, when  $b = 0$ , the prover also reveals  $r$ , which enables the verifier to check that  $z = x^2 + r \cdot n$  by performing the computation in the RNS representation (the equality  $z = x^2 + r \cdot n$  is checked modulo each of the primes  $p_i$ ), which takes quasi-linear time instead of quadratic time. More precisely, this variant is the following:

**Second Time-efficient Variant of the Fiat-Shamir Protocol:**

1. The prover generates a random  $x \in [0, n]$  and a random  $r \in [0, B]$ , and sends  $z = x^2 + r \cdot n$  to the verifier. The integers  $x$ ,  $r$  and  $z$  are represented in RNS.
2. The verifier sends a random bit  $b$  to the prover.
3. If  $b = 0$ , the prover sends  $x$  and  $r$  to the verifier, in RNS representation. If  $b = 1$ , the prover sends  $y = x \cdot s + t \cdot n$  for a random  $t \in [0, B]$ , where  $y$  is represented in RNS.
4. If  $b = 0$ , the verifier checks that  $z = x^2 + r \cdot n$ . The test is performed in the RNS representation. If  $b = 1$ , the verifier checks that  $y^2 = z \cdot v \pmod n$ .
5. Steps 1-4 are repeated several time to reduce the cheating probability.

This second time-efficient variant is more efficient for the verifier, because when  $b = 0$ , the check at step 3 is performed in RNS representation, which is of quasi-linear complexity instead of quadratic complexity. Therefore, the time-complexity of this second time-efficient variant is expected to be divided by a factor of approximately two.

**5 Cryptanalysis of the Second Time-Efficient Variant of Eurocrypt '95**

We show that the second time-efficient variant is insecure. We describe an attacker  $\mathcal{A}$  that passes the identification protocol with probability one, without knowing the private key  $s$ .

The key observation is the following: since for  $b = 0$ , the verifier checks that  $z = x^2 + r \cdot n$  in the RNS representation, the equality checked by the verifier is actually:

$$z = x^2 + r \cdot n \pmod{\Pi} \quad (1)$$

Since the attacker can choose  $x, r \in [0, \Pi]$  instead of  $x \in [0, n]$  and  $r \in [0, B]$ , we may have  $x^2 + r \cdot n > \Pi$ , and therefore equation (1) does not necessarily imply that  $z = x^2 + r \cdot n$  holds over the integers (or equivalently, that  $x$  is a square root of  $z$  modulo  $n$ ). Therefore the zero-knowledge security proof does not apply anymore, which leads to the following attack:

Since  $\Pi$  is the product of small primes, it is easy to compute square roots modulo  $\Pi$ , as opposed to computing square roots modulo  $n$ . Therefore, the attacker can generate an integer  $z$  at step 1 so that he is guaranteed to succeed if  $b = 1$ . Then if  $b = 0$ , the attacker will also succeed by computing a square root modulo  $\Pi$ , which is easy.

More precisely, at step 1, the attacker generates a random  $u \in \mathbb{Z}_n$  and a random  $r' \in [0, B]$ , and sends  $z = (u^2/v \pmod{n}) + r' \cdot n$  to the verifier. Then at step 3, if  $b = 0$ , the attacker generates a random  $r \in [0, \Pi]$ , and solves:

$$x^2 = z - r \cdot n \pmod{\Pi}$$

Since  $\Pi$  is the product of small primes, it suffices to take a square root of  $z - r \cdot n$  modulo each of the small primes  $p_i$ . If  $z - r \cdot n$  is not a square modulo a given prime  $p_j$ , it suffices to modify the value of  $r \pmod{p_j}$  without changing  $r \pmod{p_i}$  for  $i \neq j$ . This is possible since from the protocol,  $r$  is not required to belong to  $[0, B]$ . Eventually the attacker sends  $x$  and  $r$  to the verifier in RNS representation, and the attacker is successful with probability one.

Otherwise, if  $b = 1$ , then the attacker sends  $y = u + t \cdot n$  for a random  $t \in [0, B]$ , and the verifier can check that  $y^2 = z \cdot v \pmod{n}$  since  $u^2 = z \cdot v \pmod{n}$ .

Therefore, in both cases, the attacker passes the identification protocol with probability one, without knowing the private key.

## 6 Conclusion

We have shown that one of the time-efficient Fiat-Shamir variants introduced at Eurocrypt' 95 by Naccache *et al.* is insecure. Namely, a polynomial-time attacker can pass the identification protocol with probability one, without knowing the private key. Consequently, for practical

implementations, we recommend to use [4]'s first time-efficient variant rather than [4]'s second time-efficient variant, which should be avoided. We believe that our attack illustrates the importance of careful security analysis of even apparently harmless variations of known secure protocols
